

CONVENTION ON INTERNATIONAL TRADE IN ENDANGERED SPECIES
OF WILD FAUNA AND FLORA

Seventeenth meeting of the Plants Committee
Geneva (Switzerland), 15-19 April 2008

Timber issues

Bigleaf mahogany

VOLUMETRIC CONVERSION OF STANDING TREES
TO EXPORTABLE MAHOGANY SAWN WOOD

1. This document has been prepared by the Chairman of the Plants Committee.
2. As part of the 2007 Workplan and within the framework of the commitments of the DR-CAFTA (Dominican Republic – Central America Free Trade Agreement) of the Central American Commission for Environment and Development (CCAD), a CITES regional implementation workshop was held on 'Improving International Trade in the Bigleaf Mahogany (*Swietenia macrophylla*)', (Nicaragua, August 2007).
3. The workshop was supported by the World Bank, and the CCAD organizers proposed an exchange of experiences among specialists from different countries with the goal of developing practical mechanisms to boost compliance with CITES.
4. Participants in the workshop included representatives from Belize, Costa Rica, the Dominican Republic, El Salvador, Guatemala, Honduras, Nicaragua, Panama, Mexico as Chairman of the Mahogany Working Group, the Chairman of the Plants Committee, the CITES Secretariat and representatives from various NGOs.
5. The result of this workshop is a report on the *Methodology for developing national volume conversion tables (standing volume & export grade sawn wood)* and is provided at this meeting as document PC17 Inf. 3 (English and Spanish only). The key points of that document are compiled in the Annex to this present document.
6. The Chairman of the Plants Committee wishes to thank the CCAD and the World Bank for submitting the document for discussion at this meeting.
7. The Plants Committee is asked to:
 - a) study, verify and debate the contents of the Annex;
 - b) issue conclusions on the same and incorporate any relevant modifications, if necessary;
 - c) determine how to proceed with regard to the method for volumetric conversion of standing trees to exportable mahogany sawn wood; and
 - d) in line with Annex 3, paragraph 1. b), of the Decisions in effect after CoP14, advise range States of the methodology to follow.

VOLUMETRIC CONVERSION TABLE FOR MAHOGANY (*SWIETENIA MACROPHYLLA*) SAWN WOOD.
 METHODOLOGY FOR CREATING NATIONAL TABLES FOR VOLUMETRIC CONVERSION OF STANDING
 TREES TO EXPORT GRADE MAHOGANY SAWN WOOD. KOMETTER, R. AND E. MARAVI (2007).

1. Calculating the volume of export grade mahogany

One of the most common methods for laundering illegally harvested mahogany is the application of inaccurate conversion factors for calculating export grade sawn wood yields from standing timber volumes. In other words, the volumes estimated on CITES export permit applications are significantly higher than those actually produced by legally harvested trees. For this reason, in order to improve compliance with CITES, it is necessary to revise and standardize the conversion factors for standing timber and export grade mahogany wood volumes.

For example, when applying for export permits, some producing countries assume that 100 % of the standing volume is exportable. In other countries, this factor varies between 50 and 60 % of total standing volume. In a few exceptional cases, some countries have made efforts to determine conversion factors along the entire value chain. For example, dasometric analysis of data obtained during mahogany harvests in Peru and Brazil with statistical adjustments demonstrates that export grade sawn wood is approximately 20 % of the total standing volume. It is therefore estimated that between 30 and 80 % of the wood currently exported using conversion factors significantly greater than 20 % is most likely to be of illegal origin. Said timber would thus be categorized as of controversial origin. This situation has a highly detrimental impact on the sustainable use of the species, proper compliance with national and international law, the good governance of the forest sector in producer countries and the development of the forest industry in general.

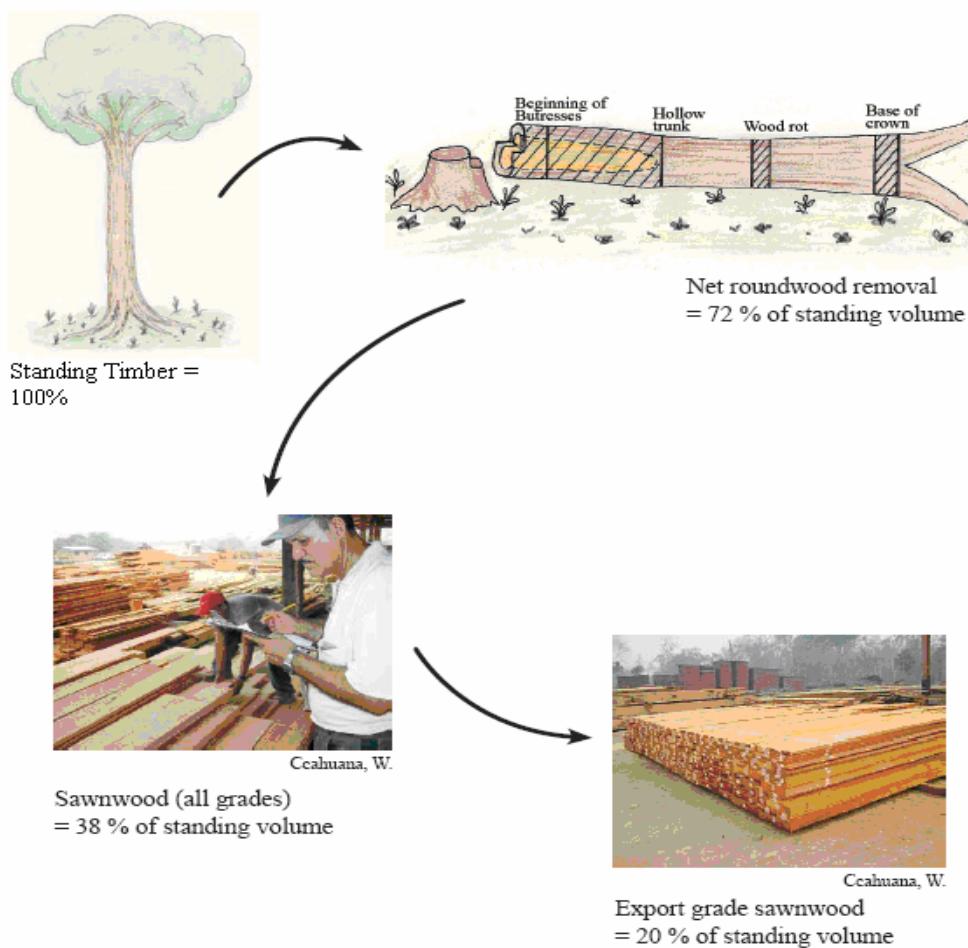

Figure 1. Relative volume reductions, forest to sawmill

2 Practical and effective options

Given the situation described, it is important to determine as accurately as possible the actual volume of exportable sawn wood produced by mahogany trees. This can be accomplished simply using dasometric principles and a volume conversion table. Based on the diameter measurement of the standing tree at breast height (DBH), the export volume of mahogany can be estimated using these tables.

This is based on the principle that in the case of the mahogany tree, there is a strong correlation between the DBH and the resulting volume of sawn wood. It is therefore possible to develop a very practical volume table in which the DBH measurement of the standing tree is sufficient to estimate immediately the volume of exportable sawn wood that can be obtained from any given tree.

Mahogany: Timber volume from standing to export volume

3. Development of national volume tables

Objective

To assist the CITES Authorities and forest management agencies of mahogany-producing countries in the region in developing national volumetric conversion tables (NVCT) for mahogany using the methodology described. The use of these simple, highly precise volumetric tables will prevent the export of greater volumes of mahogany sawn wood than can actually be produced by legally harvested trees. Once approved by the competent national authorities, these national tables will be used by stakeholders, operators, forest owners, auditors, forest management authorities and CITES Authorities.

National volume tables should be developed by following rigorously the methodology outlined below:

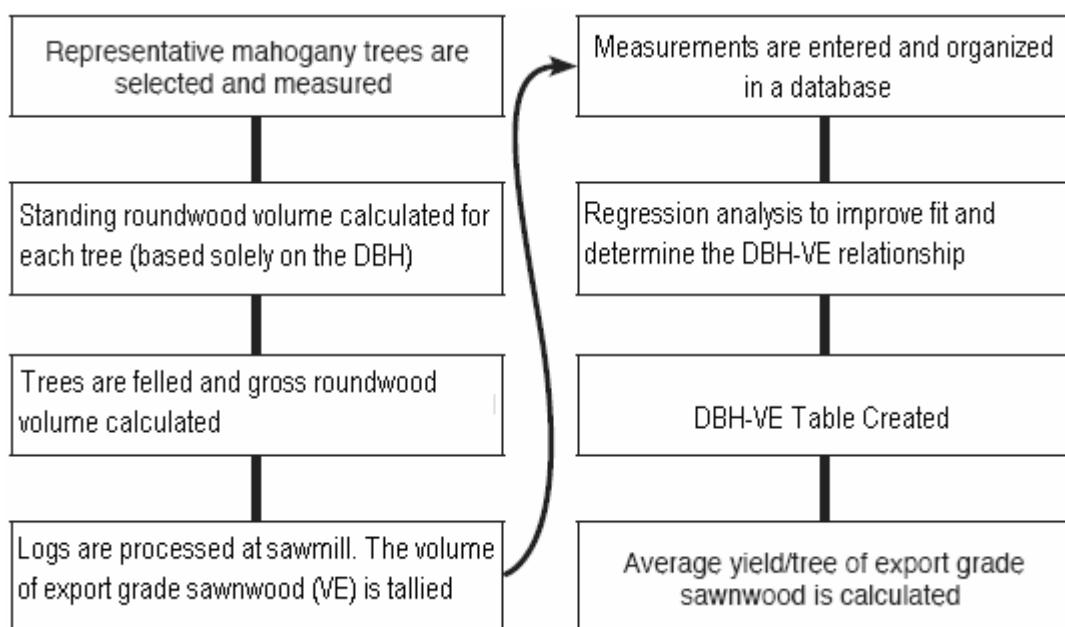

Figure 2. Methodology flowchart

Step I:

Sampling, measuring and calculating standing volume

1. Selection of mahogany trees for the preparation of volumetric conversion tables. Mahogany trees of varying diameters and dimensions should be selected at random to cover as thoroughly as possible the range of diameters, heights and shapes in the country. We recommend sampling at least 100 trees, proportionally selected from between 8 and 10 diameter classes (DC), each DC increasing 10 cm starting from the minimum allowable diameter. This sampling may be coordinated with authorized harvesting operations (forest concessions, community forests or private holdings). However, ideally the number of trees sampled should be determined statistically based on the conditions in each country.
2. Gathering the necessary data from each tree selected to calculate the real volume of each. Using a diameter tape, measure the diameter of the standing tree at 1.3 m above the ground (DBH) and at the merchantable height (MH). It is important to note that these are conventional guidelines; in practice field technicians should use their best judgment depending on the morphological characteristics of each tree.
3. Estimating the standing volume using the DBH.

Step II:

Calculating gross roundwood volume

Once the tree has been felled, take the necessary measurements to calculate the real volume of the tree, including:

- Stump diameter
- Log diameter at stump level and every two metres (d_1, d_2, d_3, \dots)
- Diameter at the cut point of the felled shaft

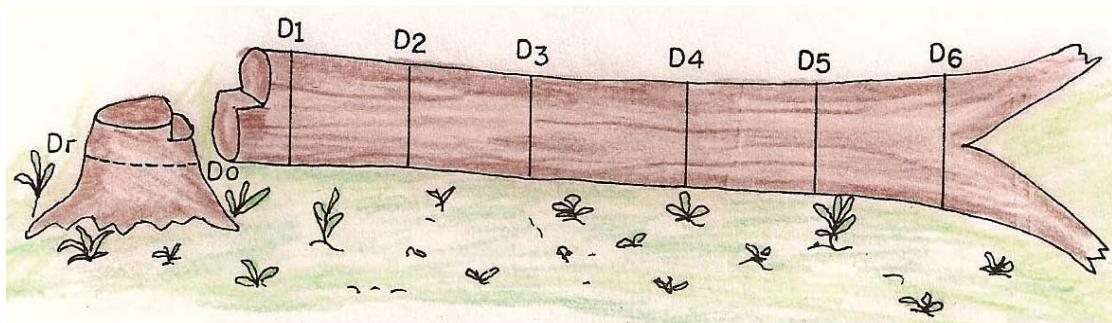

Figure 3. Log diameter measurements

4. Calculating the real volume of each mahogany tree sampled. The volume of each section is calculated using Smalian's formula. The section volumes are then added together to give the total volume of each tree.

$$V = \frac{\pi}{4} \left[\frac{D_1 + D_2}{2} \right] L$$

V = Volume (m^3); $\pi = 3.1416$; D_1 = Larger Diameter (m);
 D_2 = Smaller Diameter (m) and L = Log Length (m)

5. Measurement and deduction for defects. The magnitude (size) of any defects (hollow areas and rot) in each log section must be measured, calculating the total volume of the defects. It is important to

calculate accurately any defects (hollow areas and rot) so that the appropriate volume deductions can be made. In addition to the data and yield indices prepared by A. C. Sánchez and W. Ccahuana in Peru, we would like to acknowledge J. Grogan and J. Schulze's valuable work in the development of defect indices. Their work and studies done in Brazil have contributed significantly to the design of this methodology.

6. Eliminating unusable sections and measuring the logs from each mahogany tree that will be transported to the sawmill. Once the unusable portions have been discarded and the logs to be taken to the sawmill have been identified, they must be measured to determine the volume removed from the forest.

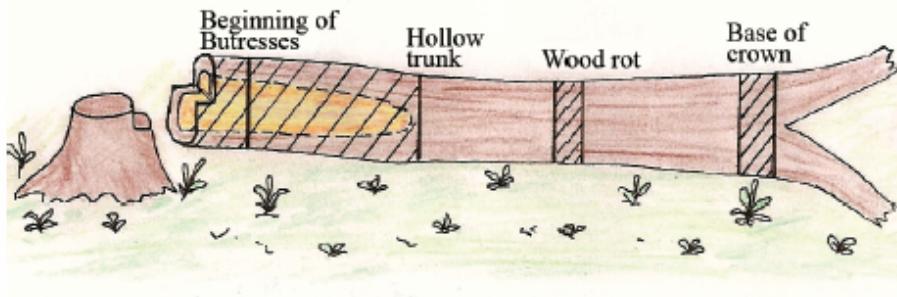

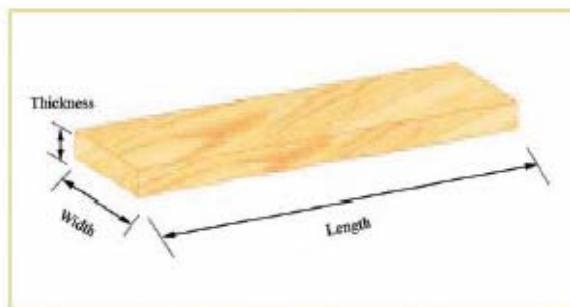

Figure 4. Volume deduction for log defects

7. Calculating the volume of each mahogany tree to be transported to the sawmill. The volume of each tree is the sum of the volumes of all logs sent to the sawmill.

Step III:

Mill processing and calculating exportable timber

8. Mill processing, grading and board measurement by grade for each mahogany tree processed.

$$V = \frac{T \times W \times L}{12}$$

Figure 5. Calculating sawn wood volume by grade where V = Volume of sawn wood (cubic feet); T = Board thickness (inches); W = Board width (inches); L = Board length (feet)

For the purpose of developing volumetric tables using this methodology, it is important to calculate accurately the volume of export grade timber.

Step IV:

Forest and sawmill data entry and organization

9. Entering and organizing data in a simple database. All data taken from selected trees in the forest and at the sawmill is organized in a database in accordance with the table below:

DBH: Diameter at 1.30 m above the ground, measured in cm on standing trees. As remarked earlier, it is important to note that these are conventional guidelines; in practice field technicians should use their best judgment depending on the morphological characteristics of each tree.

MH: merchantable height to the base of the crown, measured in metres on standing trees.

Standing timber volume: this is the total estimated volume of the standing tree calculated using the DBH, MH and the factor 0.65 (truncated cone adjustment factor). This volume is expressed in m^3 . The 0.65 factor was used in analysing the data from Peru. Each country may determine its own adjustment factor.

Gross roundwood volume: the total wood volume (m^3) of the felled tree before it is bucked into logs and transported to the sawmill.

Net roundwood volume: the volume (m^3) of the logs sent to the sawmill.

Sawn wood volume: the total volume (m^3) of sawn wood obtained from the logs entering the sawmill.

Volume of Export grade sawn wood (VE): volume of export grade sawn wood obtained from each mahogany tree.

Volumetric Conversion Factor (VCF): the ratio of export grade sawn wood divided by the standing timber volume.

We recommend that the data entry and organization be performed by at least two members of the team responsible for preparing the national table. This will ensure higher quality data entry and organization.

By way of illustration, using real, practical examples, the following table was created from a sample of 255 mahogany trees. The trees measured and documented by Sánchez, A.C. (10) were selected for exploitation at a forest concession in Peru. The defect indices used were developed by Grogan, J. and Schulze, M. (6) in Brazil, and the yield indices by W. Ccahuana (3) in Peru.

Table 1. Merchantable height and estimated volumes. (*) VE = Standing roundwood volume (4) x VCF (9). The complete dataset for this table appears in Annex 2.

Step V:

Regression analysis and development of an export grade sawn wood volume table for mahogany based on DBH.

Regression analysis is a statistical technique that reduces the margin of error in calculations of the relationship between a quantitative variable called the *dependent variable* (in this case, the export volume) and one or more independent variables, called predictors (in this case the DBH). Regression analysis is very useful for the development of volume tables, primarily because tree volume is a difficult variable to measure using conventional methods. However, with regression analysis, it can be estimated based on another variable that is easier to measure, such as the DBH, and its relationship to the volume. This analysis can be done with programs, such as Microsoft Excel or MINITAB, that are available for ordinary computers. The steps are as follows:

10. Graph the correlation between the DBH and the export volume of mahogany to determine the trends and select the model (formula) that best matches those trends, for subsequent verification. The figure below shows the levels of dispersion of the volume of export grade sawn wood for 255 mahogany trees sampled.

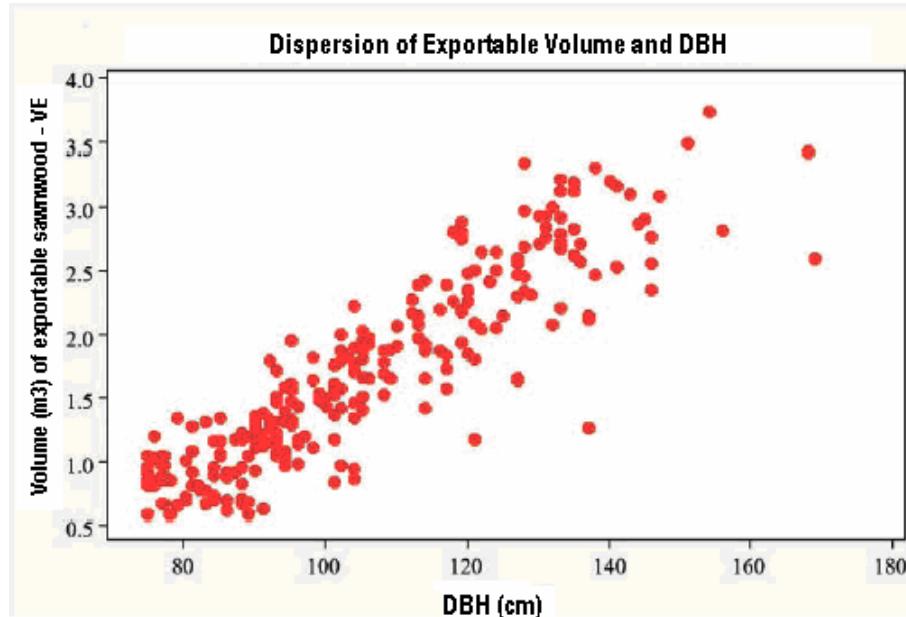

Figure 6. Dispersion of the relationship between export volume and DBH

As may be observed, the distribution of the exportable sawn wood volume per mahogany tree based on the DBH shows a marked tendency to increase. In other words, as the DBH increases, the volume also automatically increases, confirming the model recommended by Mayhew, J.E. & Newton (8). This is a single-entry model, in which only the DBH is needed to estimate the volume, as demonstrated in many studies and corroborated by Grogan, J. and Schulze, M. (6).

The following model was used for the regression analysis:

$$Y = a + bDBH + cDBH^2 \text{ [Mayhew, J.E. & Newton (8)]}$$

Where a, b and c are coefficients.

11. Determining coefficients using least squares regression analysis

The resulting equation: $VE = -2.4403 + 0.046383 * DBH - 0.00006461 * DBH^2$

12. Analyzing the equation's goodness of fit with values and tests (using Excel or MINITAB). The goodness of fit of the equation to the available data may be determined using the following values and tests:

R = Correlation coefficient, measures the strength of the relationship between two variables. The closer this value comes to 1, the greater the strength of the relationship between the DBH and the VE, and the better the equation represents said relationship.

R^2 = Coefficient of determination, measures the goodness of fit of the equation used. The closer it comes to 1, the better the DBH functions as a variable with which to estimate the VE using the equation selected.

F Test, determines whether the variable estimated with the equation (VE) has a normal variation or is influenced by the independent variable (DBH). If the calculated F value is greater than the F table value with a confidence interval of 99 %, it means the variability of the VE is highly influenced by the variability of the DBH.

Residual analysis shows the distribution of the differences between the values estimated by the equation and the actual (measured) values. The closer these differences come to 0, the closer the estimated values come to the actual values, which shows that the equation produces good estimates.

| R | R ² | F calculated | Residual dispersion |
|-------|----------------|--------------|---------------------|
| 0.897 | 0.806 | 522.15 | Good distribution |

F table value for 99 % confidence interval = 4.69

The **R** value approaches 1, indicating that there is a strong correlation between the DBH and the exportable volume. This means a change in the DBH will automatically result in a change in the VE. It can be seen that the **R²** value also approaches 1, meaning that the particular equation adequately expresses the correlation between the DBH and the VE. In other words, the value of VE estimated from the DBH is highly reliable.

If the calculated F value is greater than the F table value at the 99 % confidence interval, then the variability of the VE is strongly influenced by the variability of the DBH.

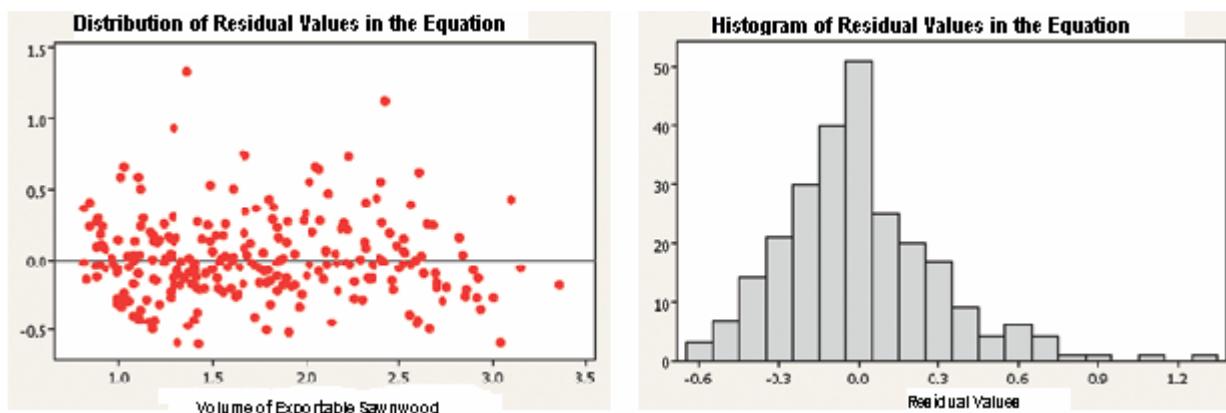

Figure 7. Distribution of residual values

Residual value = actual VE – VE estimated by the equation

It will be observed that the residual values are well distributed around zero. The histogram shows that the most frequent values are also concentrated around zero, once again demonstrating that the equation accurately predicts actual values. Graphing the two groups of values together allows us to observe objectively the goodness of fit between the values estimated by the equation and the real values.

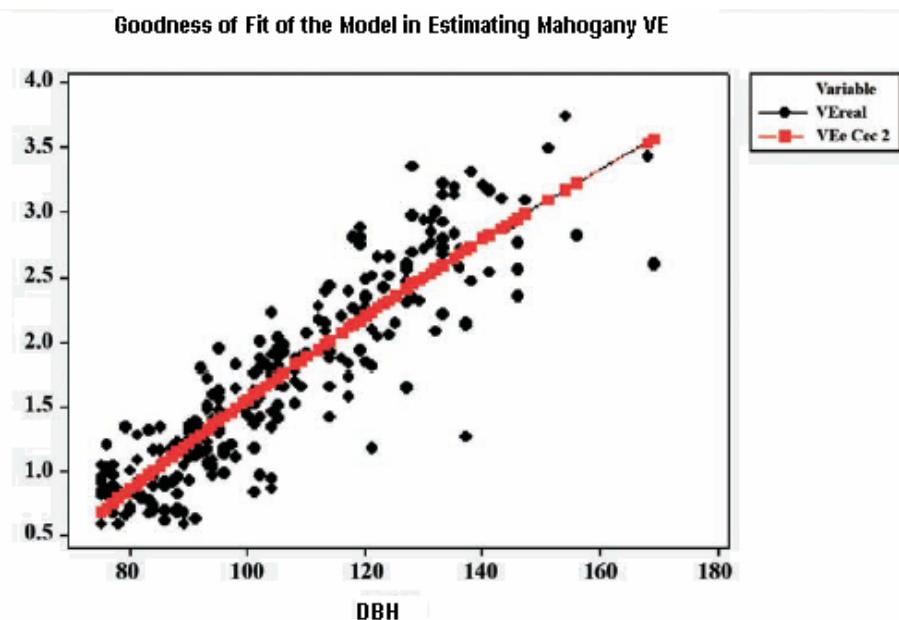

Figure 8. Goodness of fit of the model in estimating export volume

Figure 8 objectively demonstrates a good fit between the values estimated by the equation and the real (measured) values. Based on the results of these tests, we may conclude that the equation has a good fit with the observed values and we can therefore recommend its use in estimating the volume of exportable sawn wood based on the DBH. Consequently, based on these results and the regression analysis, this equation will be used to construct the volume table for determining exportable sawn wood volumes.

13. Development of the volume table for export grade mahogany sawn wood from the DBH using the selected equation (*)

$$VE = -2.4403 + 0.046383 * DBH - 0.00006461 * DBH^2$$

Table 2. Volumetric table based on DBH

| DBH (cm) | Volume (m ³) of export grade sawn wood per mahogany tree |
|----------|--|
| 75 | 0.675 |
| 80 | 0.857 |
| 85 | 1.035 |
| 90 | 1.211 |
| 95 | 1.383 |
| 100 | 1.552 |
| 105 | 1.718 |
| 110 | 1.880 |
| 115 | 2.039 |
| 120 | 2.195 |
| 125 | 2.348 |
| 130 | 2.498 |
| 135 | 2.644 |
| 140 | 2.787 |
| 145 | 2.927 |
| 150 | 3.063 |
| 155 | 3.197 |
| 160 | 3.327 |

Details of the calculation of these results will be found in the complete volume table in Annex 1.

(*) The equation selected for use will depend on the results of the analysis conducted in each country.

14. Estimating the average volume of export grade sawn wood per mahogany tree. The average is obtained by taking the average exportable volumes that was calculated in the preceding step by diameter class and the weighted average according to the proportion of trees in each diameter class.

Table 3. Volumetric table by diameter class

| Diameter class | Percentage of population in each diameter class (taken from the AOP average) | Volume (m ³) of exportable sawn wood per mahogany tree |
|------------------|--|--|
| 75 – 84 | 6.51 | 0.857 |
| 85 – 94 | 14.54 | 1.211 |
| 95 – 104 | 16.03 | 1.552 |
| 105 – 114 | 11.46 | 1.880 |
| 115 – 124 | 8.89 | 2.195 |
| 125 – 134 | 13.15 | 2.498 |
| 135 – 144 | 10.06 | 2.787 |
| 145 – 154 | 5.07 | 3.063 |
| 155 - + | 14.28 | 3.327 |
| Weighted average | | 2.131 |

As can be observed on the basis of the analysis of the data obtained from a total sample of 255 trees, the average volume of exportable wood per mahogany tree is 2.131 m³. Such a national average will provide users with an immediate idea of the origin and legality of volumes of export grade sawn wood at management unit and national levels, based on the number of verified mahogany trees in the forest.
